Rfmla.pdf

1 Raw input data

The raw input data is often in the form of a data frame. For example,

```
#-- Raw Input Data
#  cat is categorical with 3 levels: A,B,C
#  num is numerical
#  y is numerical response variable

Z = data.frame(cat=c('A','A','B','B','C','C'), num=1:6, y=rnorm(6),
               stringsAsFactors = FALSE)
Z
#>   cat num       y
#> 1   A   1  1.0240
#> 2   A   2 -0.2509
#> 3   B   3  1.0477
#> 4   B   4  1.5003
#> 5   C   5 -0.2386
#> 6   C   6  0.4949
```

has three columns, `cat` is categorical data, `num` which is numerical data, and `y` which is the response variable.

2 Formula in models

The formula interface in R allows you to make transformations of the input data frame automatically. For example, categorical (or factor) columns will generate the appropriate dummy variables.

```
lm(y~cat, data=Z)$coef
#> (Intercept)        catB        catC
#>      0.3865      0.8874     -0.2584
lm(y~cat - 1, data=Z)$coef   # remove intercept
#>   catA   catB   catC
#> 0.3865 1.2740 0.1282
```

The default behavior is to convert categorical data to a *factor* and drop the first level.

The formula interface is easy to use:

```
#- numerical data only
lm(y~num, data=Z)$coef
#> (Intercept)         num
#>     0.81179    -0.06159
```

```
#- transformations
lm(y~log(num), data=Z)$coef
#> (Intercept)    log(num)
#>      0.7775     -0.1653
```

```
#- use I() to make custom functions
lm(y~I(3*num), data=Z)$coef
#> (Intercept)  I(3 * num)
#>     0.81179    -0.02053

#- we have already seen poly()
lm(y~poly(num, degree = 3), data=Z)$coef
#>             (Intercept) poly(num, degree = 3)1 poly(num, degree = 3)2
#>                  0.5962               -0.2576               -0.2300
#> poly(num, degree = 3)3
#>                -0.3385

#- how about B-splines
library(splines)
lm(y~bs(num), data=Z)$coef
#> (Intercept)    bs(num)1    bs(num)2    bs(num)3
#>      0.7509     -0.7491      0.8162     -0.5603

#- two predictors
lm(y~cat + num, data=Z)$coef
#> (Intercept)        catB        catC         num
#>     0.43086     0.94654    -0.14018    -0.02955
lm(y~cat + num - 1, data=Z)$coef
#>     catA     catB     catC      num
#>  0.43086  1.37740  0.29069 -0.02955

#- a:b stands for interactions
lm(y~cat + num + cat:num, data=Z)$coef
#> (Intercept)        catB        catC         num    catB:num    catC:num
#>       2.299      -2.609      -6.205      -1.275       1.727       2.008

#- use . to represent everything in data
lm(y~., data=Z)$coef
#> (Intercept)        catB        catC         num
#>     0.43086     0.94654    -0.14018    -0.02955
lm(y~. - num, data=Z)$coef   # use . to include all, then remove some
#> (Intercept)        catB        catC
#>      0.3865      0.8874     -0.2584
```

2.1 model.matrix()

Behind the scenes, `lm()` is calling the function `model.matrix()` to construct the *design matrix*. The design matrix is the real valued X matrix used for calculating the coefficients. You have to pass a `formula` object into `model.matrix()`.

```
fmla = formula(y~num+cat)
model.matrix(fmla, data=Z)
#>   (Intercept) num catB catC
#> 1           1   1    0    0
#> 2           1   2    0    0
#> 3           1   3    1    0
#> 4           1   4    1    0
#> 5           1   5    0    1
#> 6           1   6    0    1
#> attr(,"assign")
#> [1] 0 1 2 2
#> attr(,"contrasts")
#> attr(,"contrasts")$cat
```

```
#> [1] "contr.treatment"
```

```
fmla = formula(y~num+cat-1)  # remove intercept
model.matrix(fmla, data=Z)
#>   num catA catB catC
#> 1   1    1    0    0
#> 2   2    1    0    0
#> 3   3    0    1    0
#> 4   4    0    1    0
#> 5   5    0    0    1
#> 6   6    0    0    1
#> attr(,"assign")
#> [1] 1 2 2 2
#> attr(,"contrasts")
#> attr(,"contrasts")$cat
#> [1] "contr.treatment"
```

Or, if you are good with data manipulation construct the design matrix manually.

```
library(dplyr)
transmute(Z, intercept=1,
          x1=num, x2=num^2,
          x3=ifelse(cat=='B',1,0), x4=ifelse(cat=='C',1,0)) %>% as.matrix()
#>      intercept x1 x2 x3 x4
#> [1,]         1  1  1  0  0
#> [2,]         1  2  4  0  0
#> [3,]         1  3  9  1  0
#> [4,]         1  4 16  1  0
#> [5,]         1  5 25  0  1
#> [6,]         1  6 36  0  1
```

Some functions (e.g., `glmnet`) do not take formulas so you will have to pass in the design matrix X directly. Another word of caution, some functions (again like `glmnet`) add the intercept automatically so you should not include a columns of ones.

The function `lm.fit()` fits a linear model from a design matrix:

```
X = model.matrix(formula(y~num+cat), data=Z)
Y = Z$y
lm.fit(x=X, y=Y)$coef
#> (Intercept)         num        catB        catC
#>     0.43086    -0.02955     0.94654    -0.14018
```

2.2 Comparison

It is always good to compare the approaches just to make sure there are no mistakes.

```
fmla = formula(y~num+cat + I(num^2) + sqrt(num))

#- lm()
beta.lm = lm(fmla, data=Z)$coef

#- lm.fit()
X = model.matrix(fmla, data=Z)
beta.lmfit = lm.fit(X, Z$y)$coef

#- direct matrix operations
beta.eq = solve(t(X) %*% X) %*% t(X) %*% Z$y
```

```
#- output
data.frame(beta.lm, beta.lmfit, beta.eq) %>% knitr::kable()
```

	beta.lm	beta.lmfit	beta.eq
(Intercept)	11.2463	11.2463	11.2463
num	5.6909	5.6909	5.6909
catB	1.3431	1.3431	1.3431
catC	-1.0617	-1.0617	-1.0617
I(numˆ2)	-0.1447	-0.1447	-0.1447
sqrt(num)	-15.7685	-15.7685	-15.7685
